Posgen User Guide

D. Haley

July 2017

1 Introduction

Posgen is a command-line only tool for the manipulation and creation of "POS" (position) files from Atom Probe Tomography (APT). These files contain a list of x,y,z and mass-to-charge data, which are in the form of a 3D point cloud (a series of points in space). Using posgen a wide variety of "operations" can be performed, where an operation is a small subroutine that works on this point cloud. Operations in posgen include geometric operations (cutting, scaling, rotating), compositional (obtain compositions or profiles, drop unranged data), file format conversions (pos↔tapsim, pos↔text), data synthesis (crystal generation), statistical analyses (clustering), etc. The program is primarily aimed at users who undertake data analysis of atom probe datasets, who would like to minimise the amount of computer programming they need to undertake.

Each operation can be connected to another allowing for a practically infinite number of combinations. By joining operations together, new datasets can be created or queried, in a rapid fashion. *Posgen* is designed to be fast, and to save having to re-write yet another data analysis tool. You can replace many complex scripts with simple *posgen* calls. For an example of using *posgen*, see the Example session6.1.

2 Copyright

Posgen is free software - you can copy, modify and distribute the program as you see fit, with no charge, within the constraints of the GNU General Public Licence v3.0. Similarly, this document is copyright under the Creative Commons 4.0 Attribution-ShareAlike licence (CC by-sa-4.0 \bigcirc). Information on how to locate the full licence terms is available in Appendix 10.3. If you have paid for this software, please request a refund and notify the Authors.

3 Installing

Posgen is provided as source-code for most platforms. You need to follow your platforms guide to installing a compiler, and building the program. For the latest instructions on how to install *posgen*, it is recommended to refer to the website http://apttools.sourceforge.net/documentation.html.

The current dependencies for *posgen*, as of June 2014 are as follows. :

• GNU Scientific Library: https://gnu.org/software/gsl

• QHull: https://www.qhull.org

• libxml2 : www.xmlsoft.org

• (not available under windows) Muparser: https://sourceforge.net/projects/muparser/

It is recommended, where possible to use your package manager to install any dependencies. Under redhat-like (CentOS, Fedora, etc) systems, ensure you install the -devel (e.g. libxml2-devel) packages to allow for source compilation. When working under Debian-like systems (Ubuntu, Mint) ensure you install the -dev package (e.g. libxml2-dev).

4 Questions

- Why would I use this program? The program is designed to speed-up data processing on your own. Without this program, when performing calculations on your own data files, you would need to write your own programs by hand. Here, you can just use posgen to do it whether you want to rotate, scale, random relabel, or perform any other common APT operation. Posgen is fully automatable, meaning you can perform the same operation (e.g. composition measurements) across many datasets. In short Posgen will save you time.
- What operating systems does posgen work with? You can use any "POSIX" compatible operating system, such as Linux and OSX. Additionally, windows is supported.
- Is there a graphical interface for posgen? At this time there is no graphical interface for posgen. It is a command-line only tool. You must write a script, in "XML" format and then give it to posgen to process.
- How do I view the output? you can view the output using any program that can open .pos files. If you don't have your own favourite, you can use the open-source 3Depict program to view and manipulate the output¹.
- I'm getting an error: I/O error: failed to load external entity "posscript.dtd". See the entry in troubleshooting, in Section 7.
- What are the units for the data files? Pos files have no natural units stored inside the file. Spaces are simply specified and interpreted by the user. By convention, datasets are normally specified in "nm", however this is not enforced by the file format.

5 Help

Whilst this document attempts to be as complete a reference as possible, it cannot fully answer all questions that one might have when using the software. Examples for most operations can be found in the examples/ folder, or online at http://sourceforge.net/p/apttools/posgen/code/ci/default/tree/examples/.

Additional help is available online at the website forums ². If posting a problem, please try to be as specific as you can regarding what you are trying to do, so we can assist as quickly and accurately as possible. If you think you have found a bug, please also use the forums to notify us - even if you are not entirely sure, and we will attempt to resolve the problem as soon as possible. If you have an operation you think could be implemented, please contact us and we can identify whether or not this can be included in *posgen*.

6 Quick start

This document forms a technical reference for the usage of *posgen*. In this section the program usage is demonstrated, with worked examples of analyses.

6.1 Example session

When running *posgen*, the command line interface is used. Without any additional "arguments", the program runs as in the following:

```
Version: 0.0.1 (revision 226:11ebe5dbeff6) Dec 2013 USAGE: posgen [-pos|-text|-tapsim] xmlfile
```

The program states that it can be run in several ways, such as posgen someXMLFile.xml, or posgen -text someXMLFile.xml. Using an example from the examples/ folder, we obtain the following (\$ indicates an interactive command line, i.e. where the command has been typed in):

¹https://threedepict.sourceforge.net - Disclosure: this program is also developed by the *posgen* authors

²http://sourceforge.net/p/apttools/discussion/general/

\$ posgen examples/cubicTest.xml
Parsing File: examples/cubicTest.xml

Running first-pass checks...OK

Processing...

Processing node: cubic (Line 6) ...Done

Parse successful

Final number of generated atoms:1670625

output mode not specified -- won't create final output posfile.

Possible options are:

-pos : Pos file generation
-text : text file generation

-tapsim : tapsim binary file generation

The program first examines the input file examples/cubicTest.xml, and after some initial checking, no errors are found in the file (indicated by Running first-pass checks...OK). The program then intially starts with no data, and rather generates the data as a cubic lattice, as specified in the example. Once generated, the end of the input file is reached, and no further operations are done. The number of atoms at the end of the dataset is reported, however as no option for output is given, the program exits.

Using the following command, we request that the result be printed as text. This can result in a very large output.

_	_ ,				
\$ posgen	-text	ext examples/cubicTest.xml			
0	0	0	1		
0	0	0.405	1		
0	0	0.81	1		
0	0	1.215	1		
29.97	29	9.97	118.665	1	
29.97	29.97		119.07	1	
29.97	.97 29.97		119.475	1	
29.97	29.97 29.97		119.88	1	

This output can be saved to a file, in either pos, tapsim or text format. Here we save the data as pos^3 .

\$ posgen -pos examples/cubicTest.xml > outputFile.pos

The resultant file appears as in Figure 1 - the cubic lattice is visible in the inset, and the overall bounding box for the dataset is visible from the main figure :

³Saving to non-text formats (e.g. .pos files) using the " ξ " notation under windows may result in a corrupted file. This is due to Windows' endline translation. Windows users should use the internal save routines, e.g. possave

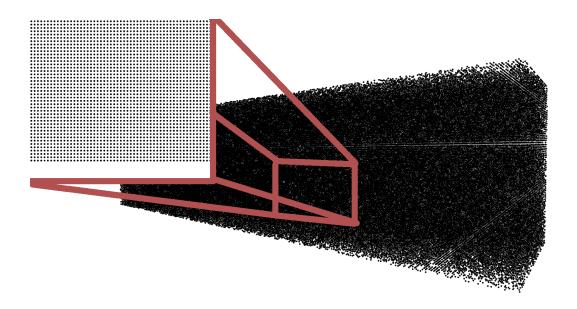

Figure 1: Cubic dataset generated from cubicTest example

7 Troubleshooting

This section outlines some problems and their solutions, for problems that have been encountered by existing *posgen* users.

7.1 DTD missing

When using the program, I get the following error:

I/O error : failed to load external entity "posscript.dtd"
<!DOCTYPE posscript SYSTEM "posscript.dtd">

– This "DTD" file contains the list of available operations for posgen, and the syntax for each. The file is normally shipped with *posgen* and is required for the program to function correctly. Either put this file in the same path (folder) as you are currently using, or have your administrator install it into your XML catalogue,

The program is looking for this "Document Type Descriptor" (DTD) file, which tells it how your input "xml" files are supposed to be structured. This file helps ensure that the input is well-formed prior to running the analysis and is shipped with the *posgen*. If the posscript.dtd file is not in a search location (such as the program, or working directory), then it is unable to perform this check. You need to either:

- Place the .dtd file which is shipped with the program somewhere where it can find it, such as the program folder or working directory, or
- Provide the complete path to the DTD using relative or absolute path values (e.g. for unix-like systems;
 - <!DOCTYPE posscript SYSTEM "/home/user/path_to/posscript.dtd"\> or, under windows: <!DOCTYPE posscript SYSTEM "C:/Users/name/PATH_TO/posscript.dtd">), or
- Under unix platforms, provide an entry for the DTD file in your XML catalogue, or
- Set the XML_CATALOG_FILES environment variable [11].

We do not recommend trying to copy it from somewhere, as the file contents can change between posgen versions.

7.2 Files in other directories

When running *posgen*, sometimes it is desirable to be able to run the program from a different folder as to where the program or data is actually located, or load data which is not in the working directory. You can either

- Use relative or absolute pathnames for the program, e.g. "C:\PATH TO\posgen", and
- where required, in your input XML file use relative or absolute paths⁴

To troubleshoot this, consider where your working directory⁵ is, and where the files are respectively. Failing this working at all, you can use file-links (windows too).

 $^{^4 {\}tt https://en.wikipedia.org/wiki/Relative_path}$

⁵https://en.wikipedia.org/wiki/Working_directory

8 Operations

This section outlines the various "operations" that are provided by *posgen*. Each operation allows for the manipulation of datasets in a specific ways, depending on the operation type. An *Operation* takes in the data from the previous *operation*, forming a chain 2. In this section, and for each operation, a short example of the tag usage itself is given with some brief details about what the operation does. Complete example files can be found in the *examples*/ folder in *posgen* packages.

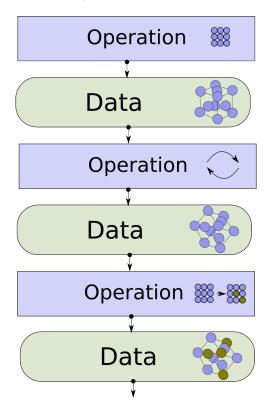

Figure 2: Chain of operations modifies data from previous operation, linking these together allows for novel analyses and data volumes to be constructed

The operation files are in XML format, and are directly human readable – thus it is possible to hand-write these files using a text editor⁶ As a short technical note, the XML syntax is largely specified in the DTD [8] file that is shipped with posgen. This file enforces the syntax allowed in the XML file.

8.1 Information

8.1.1 posinfo

This operation details some information regarding the current possfile that is in-memory. It does not modify the current data in any way. Information such as the minimal axis-aligned bounding box, number of ions and basic per-species counts can be obtained using this operation.

Example: By using a <posinfo/> or <posinfo rangefile="myrangefile.rng"/> operation, the following output can be generated.

Dumping pos information Ion Count: 1213560 Pos File limits

Min: (0.000120085,1.32434e-05,1.14832e-05) Max: (40,30,30)

 $^{^6\}mathrm{We}$ recommend to use an editor with syntax colouring, such as Notepad++http://notepad-plus-plus.org/.

When using <posinfo/> alone, the number of ions in the dataset (at that point in the script), and the bounding box (lower and upper corner) are shown. By providing an additional (and optional) range-file, using this syntax: <posinfo rangefile="myrangefile.rng"/>, information about the number of atoms in each range is shown.

```
Dumping pos information
Per Ion:
A: 1213560
B: 0
Per Range:
A: 0.5 , 1.5 1213560
B: 1.5 , 2.5 0
```

8.2 Generators

The generators allow for the creation of lattices from several predefined tile sets. At time of writing, only a limited number of crystal systems are available.

8.2.1 cubic

The cubic operation creates a fixed simple-cubic lattice within a specified bounds, and of a specified mass. The lower bound for the repetition of the crystal is (0,0,0), and the upper bound is given by the
bounds x="someval y="someval" z="someval"/>". The cube unit-cell length is set via the "A" spacing value. Only a single mass can be assigned for all points, as all points in a simple-cubic lattice are self-similar under translation (*i.e.* there is only one unique location in the crystal). The index must be (000) for the mass definition.

As an example:

8.2.2 fcc

This generator creates an FCC crystal lattice. Similarly to the cubic lattice, the tiling is performed in a rectilinear manner in 3D space. The masses for each unique position in the unit cell of the FCC crystal is specified via the <atom ··· />. The positions that can be specified are the (000), (202), (220), and (022) positions. The (000) is the corner position, and the remaining three are the three perpendicular faces, these are mandatory. The lattice parameter and bounding colume can be set using the <spacing>····</spacing> and the <bound x="value" y="value" z="value"/> attributes.

As an example, the following is given:

8.2.3 spatrand

This function generates spatially random data within a rectangular bounding box. The randomisation implies that there is no correlation between point's spatial positions. The only parameters that affects the spatial coordinates in the dataset are the density value, ρ , and the bounds for generation. The mass data assigned to each point can be set by adjusting the count and atom parameters.

A simple example snippet is as follows:

This example generates a dataset from (0,0,0) to the (40,30,30) coordinate with a spatial density of 33.71^7 . Note that for this dataset the **index** attribute is ignored for this operation. The mass and count occur in pairs, and indicate the relative fraction of atomic masses to assign. The total sum of counts (in this case, 1+2=3) is used to normalise each count, generating a composition that is approximately $\frac{1}{3}$ mass 21, and $\frac{2}{3}$ mass 22.

As the points are randomly generated, the number of *total* points is computed, and thus fixed between runs. The position and mass assignments (including composition fraction) will change randomly (as a binomial distribution) across repeated runs of the program. This can of course be locked by setting a fixed seed (Section 8.4.6) before this operation.

8.2.4 generic-rect

The generic-rect operation allows for a user-specifiable generic rectangular unit cell to be provided. Users can provide the atomic coordinates, and then the operation will proceed to tile the given unit cell across 3D space. Care must be taken that duplicate points are not generated (due to repeated tiling at walls), or that duplicate points are removed, such as via a <cleanup/> operation (Section 8.6.1).

To specify an individual atom's XYZ coordinate, in fractional values [0,1] are used, and the mass must also be supplied. The volume to which the fractional coordinates are in reference to is given by the <spacing>..../spacing> parameter. The <burn dx"</pre> y="dy" z="dz"/> specifies the rectangular volume in which the lattice will be generated.

An example which creates a simple rectangular lattice is given:

⁷There can be a slight difference between the requested and the generated density, due to the requirement that only whole points can be generated

8.3 Loading and Saving

8.3.1 posload

This operation allows for the loading of an arbitrary "position" file (POS-file). The POS file format is specified in Appendix 10.2.1, and contains XYZ and mass data. Previous data is appended to, but otherwise unaltered.

The only required parameter is the path to the file, in either relative or absolute form. URLs are not allowed. If the file cannot be found, processing will halt. An example is as follows:

```
<posload file="somefile.pos"/>
```

8.3.2 possave

This operation allows for the saving of the current in-memory data for *posgen* to a file. The only parameter required is the output filename. Upon completion, a complete pos file is generated at the specified location. **Warning:** *files will be overwritten without notice*.

An example is as follows:

```
<possave file="somefile.pos"/>
```

8.3.3 file

This operation allows for exporting or importing data to and from several specialised file formats. To specify the format to use, the "format" attribute, which can then be set to the desired file format from the following list. The "issave" attribute must be set correctly to cross-check the users desired intent.

- dl_poly (write only)
- dl_poly_history (read only)
- xyz (write only)

There is undoubtedly loss of information as the data stored in a pos file is radically different to that stored in these custom formats.

In dl_poly mode, the periodic bound value is optional (either bound or periodicbound must be specified), and is used for writing DL poly files only. If used, this will cause the file to be saved with a different periodic boundary conditions box. This can be set to either "tight", or "padded". Alternatively a box between 0 and some given value can be set with the bound tag.

8.3.4 tapsimload

This operation allows for the loading of TAPSIM[5] formatted binary files. Only the input filename is required as a parameter. Existing data is appended to, but not cleared.

```
<tapsimload file="sometapsimfile.bin"/>
```

8.3.5 textload

This operation allows for the loading of delimited text files. Each file must have 4 columns of data, and be delimited using a chosen delimiter. The text data must have four columns, which are interpreted as x,y,z and mass respectively. Allowed column separators are given by delimiter="someChars"/>, and more than one delimiter may be given.

A sample dataset that can be loaded is given below, using the space character as the delimiter:

```
colA colB colC colD
1 2 3 4
1 2 3 1
2 5 2 1
```

This can be loaded with (assuming the data is stored in *somefile.txt*):

```
<textload file="somefile.txt" delimiter=" "/>
```

or, if multiple delimiters are needed (here comma, colon and space) the following can be used:

```
<textload file="somefile.txt" delimiter=",: "/>
```

8.3.6 store

The store operation allows the current dataset to be saved using a specified name. Saved datasets can be later recalled using \rcell ···/>. This can be useful if one, for example, wishes to perform repeated calculations, or alterations to a dataset, and wishes to save the original for subsequent processing. The dataset will be saved using the *name* parameter.

To save a dataset, use <store name="somename"/>. Optionally, the current data can be erased after the save by providing the *clear* parameter, e.g. clear="true". An example is as follows:

```
<store name="uniquename" clear="true"/>
```

As a technical point, the data is saved to disk, and will no longer be stored in memory after the store is complete. There are two reasons for using this in preference to a **possave** operation. Firstly, the stored data will be cleaned up automatically at the end of the program run. Secondly, there will be no name clashes between instances of the programs, allowing for multiple copies of *posgen* to be run on the same XML file at the same time, without risk of data corruption due to reading/writing to the same file simultaneously.

8.3.7 recall

This allows for previously named datasets to be restored back into the current state. The name parameter sets the stored data name. The current data can be erased prior to recalling by using the option cleardata="true", and the name can be deleted (i.e. it cannot be recalled again) by using clearname="true". The clearname and cleardata attributes are optional, and default to false. The recall operation can only be used if a previous <store ··· /> operation has been given, using the specified name parameter. An example is as follows:

```
<recall name="uniquename" clearname="false" cleardata="false"/>
```

This can be used in a similar fashion to the posload operation, however as with the **store** operation, there is not risk of data corruption using this method with multiple processes, and data will be automatically cleared.

8.4 Generic Data operations

8.4.1 clear

This operation erases the current data. Data stored using <store/> is not affected. There are no options. To use this operation, simply use the <clear/> element.

8.4.2 extractfield

This operation allows the output of a specific field (x,y,z or m) from the dataset to a text file. The output file is specified using the file="somefile", This can be used, for example, to process data with other applications. To select the desired field to extract, the attribute field=integer"/>, where the digits 0,1,2,3 correspond to x,y,z and m respectively. Optionally a min and max value can be specified to limit the data that is extracted.

Note: no warning will be given when writing to the file. Any existing file will be replaced. An example is as follows:

<extractfield file="somefile.txt" field="2" min="100" max="200"/>

8.4.3 massclip

The <massclip /> operation allows for the cropping of a dataset by its mass-to-charge value. There are two parameters, min and max, which set the lower and upper limits for cropping. Only points whose masses lie within these limits (inclusive) will be retained.

8.4.4 mathtransform

Note: This is not available for windows based systems

This operation allows for the application of an arbitrary transformation equation to each field. The operation utilises the MuParser library. As such, the full syntax is given by the muParser documentation⁸. Each point is operated on independently, so "array" type operations (mean, std deviation, min, max) will not work. However, operations that utilise multiple fields will work (e.g. $x^2 + y^2$), as will operations such as log and exp, trigonometric operations sin and cos are supported. To assign a field, the variables x, y, z and m can be used. An equation such as $\operatorname{sqrt}(x)$ is valid. Other valid equations could include $x^2 + z^2 + \exp(m/10)$, or similar. The result of the equation is stored in the value specified in field, which can be 0, 1, 2 or 3. These values correspond to xyz and mass respectively.

An example is as follows:

<mathtransform field="0" expression="sqrt(x^2+1)"/>

8.4.5 setfield

This can be used to set any desired field to a constant value. Valid fields are 0,1,2 or 3. These values correspond to xyz and mass respectively. As an example, for setting the "y" field, the following is given:

<setfield field="1" value="12.4"/>

8.4.6 seed

This operation does not modify data directly - instead this sets the so-called *random seed* used when generating random sequences. The generated random sequences determine, for example, how shuffling is performed, how spatially random data is generated, and similarly controls any computationally "random" process.

As computers follow fixed algorithms, true randomisation is complicated, and outside the scope of this document. For here, it is sufficient to say that a single number - the "seed" sets the randomisation sequence for each time the program is run. Normally this is selected from the current clock time, and will change between runs. This operation allows overriding this seed value. Only operations after the seed are affected. To set the seed value, simply use <seed value="123"/>, where 123 is replaced with the desired seed. Often the actual value itself does not matter, as it may only be desired that the exact same operation is performed each time the program is run.

⁸http://muparser.beltoforion.de/

8.5 Geometric operations

8.5.1 arraysplit

This operation divides the dataset into rectangular regions, and will save each region as a new file. There are two modes possible. In the first mode, "dimension", a fixed width for the clip is used - the size of the rectangular region to be cropped is given, using the x dimension via <x value=""> (and similarly for y and z). In the second "count" mode, the x,y,z values are interpreted as the number of cuts to make, and the dimensions of each cut are determined by the minimal box that contains all the current data and the number of cuts requested.

To set the file names for output, the <naming prefix="someprefix" suffix="blah"/> values can be used. Whilst the prefix is mandatory, the suffix is optional, and defaults to ".pos". This will save the files in the form someprefix-number.blah. This should be used after setting the xyz values. After this field is set, optionally a <count/> value can be provided, to enable the "count" mode - without this, the "dimension" mode is used.

An example of using the "count" mode is given - this will cause the dataset to be split into 125 files:

8.5.2 clip

The clipping operation can be used to crop regions of the dataset based upon the x,y,z coordinate of points. Allowable clipping entities are:

- sphere A simple sphere, given by origin and radius.
- box an axis-aligned box, specified by two coordinates.
- plane A 2D plane in 3D space, specified by normal (in spherical coordinates) and a point on the plane.
- cylinder An arbitrarily oriented cylinder.
- mesh Any closed triangle mesh, in GMSH format[1][9]. Triangle orientation must be self-consistent, and mesh must be "manifold" (realisable as a "simple" 2D surface holes are permitted).

Normally, the interior of the clipping object is retained, however optionally, each clip operation can be inverted, using the invert attribute. i.e. the interior is clipped (and exterior retained) by using the invert attribute.

Each primitive is defined slightly differently. For the sphere primitive, the following example is given:

A box can be described via the x/y/z for two corners:

A cylinder is given by specifying the origin, the axial vector (from centre to one end), and the radius of the cylinder:

A mesh object must be a triangle mesh of GMSH form, and can be loaded as in the below. The mesh may be optionally recentred around the origin (by vertex-based weight).

```
<mesh file="somemesh.msh" recentre="false"/>
```

A full example is given here:

8.5.3 geotransform

This operation allows for simple linear transformations of the x/y/z data, such as rotation, translation and scaling. The layout for each operation is slightly different, and is presented here separately - however these individual sub-operations must be present inside a $\operatorname{geotransform} \cdot \cdot \cdot / \operatorname{geotransform} \cdot$. Each sub-operation (rotation/translation/scaling) can be performed in sequence, without requiring a new geotransform operation. All transformations use a right-hand coordinate convention.

rotation: this operation performs a rotation, centred at the origin and around the specified vector, using vector-angle notation. Rotation angles are given in radians, and the rotation is anti-clockwise as viewed from the positive end of the rotation axis. An example of rotation (90 degrees around the 111 axis) is given below:

translate: Translation can be performed in two ways, either by translating the "centre-of-mass" (assuming each point has unit mass) to the origin, or by specifying the translation vector. The translation vector will be added to each point in the dataset. The translation can be performed as follows:

For the centre-of-mass specification, the following example is given:

scaling: Similarly to translation and rotation, scaling of the entire dataset can be performed using scale. Scaling is performed around the origin, and can be performed anisotropically, with differing X, Y and Z scaling.

A complete example, with sequential translate, rotate and scale transformations, is given below:

```
<geotransform>
    <translate>
      <centreofmass/>
    </translate>
    <rotate>
      <x value="1.0"/>
      <y value="1.0"/>
      <z value="1.0"/>
      <angle value="1.50708"/>
    </rotate>
    <scale>
      <x value="2.0"/>
      <y value="2.0"/>
      <z value="2.0"/>
    </scale>
</geotransform>
```

8.5.4 noise

The noise operation allows for the addition of randomised positional noise to data. Noise operations are useful for determining how robust algorithms are in the presence of spatial uncertainty and can be used in many statistical analyses.

Either White or Gaussian noise can be added using this operation. For white noise, a random vector contained within the box $\pm dx$, $\pm dy$, $\pm dz$ is added to each point the data. For Gaussian noise, the x/y/z values refer to the standard deviation of a normalised Gaussian, from which the noise vectors will be computed. Examples of white and Gaussian noise are given below:

8.5.5 posset

This operation performs a so-called "set" (as in set-theory⁹) operation on points S(A, B). Currently supported operations are "subtract" and "intersect". For the purposes of the set operation, only the positions (the xyz, but not the "m" value) is considered. The current in-memory data is considered as the A set, and a specified file is considered to be the B set - the result of the set operation is stored in-memory.

8.6 Data quality

8.6.1 cleanup

The cleanup operation performs a simple "tidying" of the dataset. At this time, the only modification made to the data is the removal of points whose x/y/z values overlap, within some tolerance. To use the cleanup operation, use <cleanup removeduplicates="true" duplicatetol="someTolerance"/>, where someTolerance is greater than zero.

8.6.2 surfremove

This operation removes the surface of a dataset, by a convex-hull reduction method. The convex hull is computed, and re-scaled around its centre of mass, such that the specified removal distance is guaranteed to be removed. This can, for example, be combined with the pointdensity and posset commands to remove surface artefacts (at the cost of statistics).

The only parameter for the surfremove operation is the distance to be removed, and is specified as an attribute, i.e. <surfremove value="somevalue"/>.

8.7 Randomisation

8.7.1 randreplace

The randreplace operation performs random replacement of the "m" value (xyz-m) associated with each point. Each point can be randomly assigned a new mass, as given using the mass attribute. To set the fraction of points replaced, a frac option must be given. Note that the fraction is applied randomly (ie, each point has a probability of frac for reassignment) - thus the number of points that are reassigned

⁹https://en.wikipedia.org/wiki/Set_(mathematics)

is governed via a Binomial distribution, and can vary slightly from run to run. The frac value must lie in the range [0, 1]. An example is given below:

8.7.2 randrm

Random removal of ions from within the dataset - each ion is examined in the dataset and randomly erased. The only parameter is fracrm="value", where value lies between zero and one, e.g. <rardrmfracrm="0.5"/> will remove approximately 50% of the points in the dataset.

Note that the random selection is performed per-ion, and the result will randomly change from run to run - both in which points will be removed, and in the number of points that are removed (which is governed by a binomial distribution. If it is desired that the same "random" removal is performed each time, the random "seed" must be set, as detailed in Section 8.4.6.

8.7.3 shuffle

Shuffle simply randomly-orders the in-memory points - this can be useful when writing data to a file for input into programs which otherwise are order sensitive. The spatial positions of the data, and the associated mass information is unchanged. The only allowable usage is <shuffle/>.

8.8 Compositional operations

8.8.1 range

The ranging operation applies a so-called "rangefile" to the current data, and uses this to drop points whose mass value does not lie within a set of specific "ranges". Each range refers to a region of the mass between some lower and upper bound. The rangefile must be a valid "RNG", "RRNG" or "ENV" file (See Appendix 10.2.2) - files which are not correctly formatted will be considered an error and processing will be halted. The file type (RNG/RRNG/ENV) will be automatically detected, so there is no requirement to specify the rangefile type.

The mass ranges can be inverted, by using the <code>invert="false/true"</code> attribute- if this is supplied (and set to <code>true</code>) then points whose values correspond to the ranged mass values are dropped, and the unranged data is kept.

The usage for this operation is as follows:

<range file="someRangeFile.rng" invert="false"/>

8.8.2 cluster

The cluster operation performs a clustering analyses. The only currently supported algorithm is the Maximum-Separation method, (<algorithm value="maxsep"/>) as described by Vaumousse [10], Hyde [3] and Stephenson et al [6].

In the simplest mode of operation, "Core" (or "solute") points can be used to generate cluster backbones, by linking together points that lie within a specified $d_{\rm max}$ (sometimes referred to as $d_{\rm link}$) of one another. These cluster backbones can have non-core (aka "bulk" or "matrix") material attached to them by using the $d_{\rm bulk}$ parameter - any points that are within $d_{\rm bulk}$ of the cluster backbone's points will be added to the cluster. Additionally, the "erosion" post-processing step of Vaumousse, and the "classification" pre-processing step of Stephenson is supported, via the $d_{\rm erosion}$ and $d_{\rm classify}$ values.

The attributes that must be specified are as follows:

- dclassify value="number" knn="integer" The value specifies the "classification" distance, as described by Stephenson. To disable this step, set the value to zero. This parameter can be used to refine which points may be utilised as clustering "core" points. The knn attribute specifies that in order to be allowed, this k-th nearest neighbouring point must be found within the core radius. If not, it cannot be used as a "core" clustering point.
- **dmax value=**"number" This value specifies the distance within which points that are nominated to be "core" points may be found, in order to be considered part of the same cluster.

- **dbulk value=**"number" This value specifies the distance from a cluster within which "bulk" points, can be considered to be part of that cluster.
- **derode value=**"number" This value specifies how much distance from non-clustered material that bulk points otherwise associated to clusters should be rejected from clustering.

This allows for the extraction of clusters of points from datasets, and can be used in conjunction with the <relabel/> operation to allow for statistical examination of cluster distributions against randomised distributions, similar to the method of Stephenson [6].

A rangefile is mandatory, as specified via a <range file="somefile.rng"/> element. This must be followed by a <core> ··· </core> section, and similarly a <bulk> ··· </bulk> section, which contains a list of <atomtype symbol="RangeSymbol"/> elements.

Some additional, but optional parameters are available. These allow for finer control over the clustering process and its output. If given, these must be given in the order as shown here (omissions are permitted).

- <sizeclip nmin="integer" nmax="integer"/> The minimum/maximum allowable size of a cluster. Clusters less than this size will be rejected from the analysis. Both nmin and nmax are optional, and one or the other can be omitted.
- <unranged forstats="true/false" foroutput="true/false"/>" Should unranged (not part of core or bulk data) be included in cluster achulations or output? If foroutput is set to true, then unranged data should appear in the cluster pos file. If forstats is set to true, then unranged data will be counted in the cluster statistics. These both default to false.
- <clusterstats core="true/false" bulk="true/false" percluster="true/false" file="filename"/>
 - This optional parameter causes the program to emit information regarding the statistics of the clustering process, such as the number of ions of each type in the clusters and the radius of gyration. If percluster is set to true, then additionally the centroid of each cluster will be printed. This data can be quite large, so optionally, this can be saved to a text file, by supplying the file="filename" attribute. Other than for file, each attribute is required.
- <unclusterstats file="filename"/> This option will cause the program to print out the number of ions that were not counted as part of a cluster. The file attribute is optional, and without this, the result will be printed to the terminal.
- <sizedist file="filename"/> This option will cause the program to generate a cluster size distribution. The distribution is the number of clusters for each number of "core" atoms. The file attribute is optional, and without it the results will be printed to the terminal.
- <clustered-pos file="filename" retain="true/false"/> This option has two effects. If the file attribute is specified, then points that are considered part of the clustering are saved to the named file. If the retain parameter is set to false, then the output of the clustering is dropped from the in-memory dataset. This means the clustered data will not be passed on to other operations. If the retain value is omitted, it defaults to true.
- <unclustered-pos file="filename" retain="true/false"/> Similarly to the <clustered-pos ...> element, this allows for the saving, or retainment of the ions that are not considered part of a cluster.
- <clusterid offset="value"/> the clusterid tag will assign the output cluster file's masses with a numerical value that will label each cluster individually (0, 1, 2 ...) etc. An offset can be optionally set to specify the initial value (offset, offset + 1, offset +2 ...). The offset does not need to be an integer. By using this value, you can for example, merge a cluster ID file and a normal one, by shifting to higher and higher masses. Note that there is a limit on the number of clusters that can be uniquely labelled in this manner (around 10⁷), which is a limitation of the pos file format.

An example of using the clustering operation is given below:

```
<cluster>
        <algorithm value="maxsep">
                <!-- classification (pre-cluster) dist; zero to disable this step-->
                <dclassify value="0" knn="1"/>
                <dmax value="0.5"/> <!-- Max sep dist, may also be called dLink -->
                <dbulk value="0.2"/> <!-- also known as envelope-->
                <derode value="0.2"/> <!-- erosion distance-->
        </algorithm>
        <range file="../AB.rng"/>
        <!--select ions for cluster core (aka solute)-->
        <core>
                <typelist>
                        <atomtype symbol="B"/>
                        <!-- Could have more ions here, like so:
                        <atomtype symbol="C"/>
                        <atomtype symbol="F"/>
                                   -->
                </typelist>
        </core>
        <!--select ions for bulk (aka matrix)-->
        <bulk>
                <typelist>
                        <atomtype symbol="A"/>
                        <!-- Could have more ions here, like so:
                        <atomtype symbol="C"/>
                        <atomtype symbol="D"/>
                                   -->
                </typelist>
        </bulk>
        <sizeclip nmin="2"/>
        <clusterstats core="true" bulk="true" percluster="true" file="cluster-stats.txt"/>
        <unclusterstats file="unclustered-stats.txt"/>
        <sizedist file="sizedist.txt"/>
        <clustered-pos file="cluster.pos" retain="true"/>
        <unclustered-pos file="uncluster.pos" retain="true"/>
```

8.8.3 Cluster sweep

</cluster>

Sometimes it is useful to see how changing a parameter affects the output of a clustering operation. To do this, one could simply use multiple cluster elements, like so:

This would work, but is very verbose - more importantly would be time consuming, and you need to extract the output somehow, so it doesn't overwrite it at each time. To make this easier, there is a clustersweep operation, which performs 1D sweeping of the chosen function. Data structure generation is performed once, so this is much faster than repeating the calculations each time.

Sweeping is linear, and you specify start, end and step size for the parameter. At time of writing, the following parameters are supported:

- dbulk
- dmax

You still need to specify all parameters values (e.g. dmax value) in the cluster operation, but the one being swept will be overwritten.

8.8.4 composition

NOTE: The background correction feature is experimental, use at your own risk.

This operation computes the total composition of the dataset, using the ranging assignments provided. A rangefile must be provided, via rangefile="somefile" attribute. Background correction can optionally be performed. Currently multiple ions cannot be automatically split into their components. Composition data can be in un-normalised (raw count) or in normalised form (with counts) by setting the count="0/1" parameter. Normalised results are given in atomic percent.

At this time, the only allowable background correction modes are mode "0" - no correction, and mode "1" - which is a TOF-noise correction.

The TOF-noise correction works on the assumption that the background is formed is flat in TOF space, and when converted to mass-to-charge space (using a sqrt type extraction, typical for APT data) the noise follows a simple analytical curve (equation below, where k_{fit} is the estimated noise intensity, and m is the mass). A region for noise selection must be given, to allow for background fitting, which the start and end are given as backstart="value" and backend="value" - the start value must be lower than the end. The attribute backbins value="value" determines how data is to be binned when performing the TOF fit and statistical test; a value of no less than 10, and usually 20 is recommended. If any peaks are within the noise region, the statistical test will fail, and the compositional estimate will be aborted.

$$N_{\text{background}} = \frac{k_{\text{fit}}}{2\sqrt{m}} \tag{1}$$

Integrating this equation yields a total noise within an [A, B] range as:

$$N_{\text{background}} = k_{\text{fit}} \left[\sqrt{m} \right]_a^b \tag{2}$$

This total noise is subtracted from each range to determine the final count, and thus composition. Statistical checks (Anderson-Darlington) are performed to ensure that the region selected for background correction is Gaussian when converted from m/c to TOF-space - an error is reported if the data is not Gaussian. For APT most users, fitting between 1.5 and 2 should yield good results, as no peak is expected at this mass.

An example of usage is as follows:

8.8.5 compprofile

This operation computes a composition profile from a dataset. At this time only spherical profiles (radially increasing) are supported - if requested, we may implement axial cylindrical profiles. The profile result is saved to the file specified in the mandatory file attribute.

For spherical profiles, the properties that can be set are are:

- vector: Position vector to sphere origin.
- scalar: Radius of sphere.

Finally the number of bins to take is given by <nbins value="integer"/>. The step size is computed automatically.

An example of a spherical composition profile is given here:

8.8.6 relabel

The relabel operation performs a random shuffling of the "m" value across the spatial positions, commonly referred to as "random relabelling". Commonly this operation is used for random-comparator statistical trials, particularly when looking for spatial correlations within a dataset (shuffling provides a good null-comparator) [7].

This operation has no parameters, and the only usage is given below:

```
<relabel/>
```

8.8.7 proxigram

NOTE: This feature is experimental, use at your own risk. The proxigram operation computes either a density or concentration profile as the distance from some surface. Each point in the point-cloud is assigned a so-called *signed distance* from the surface, and a histogram of these distances are generated (which is the proxigram function [2]). To do this, a mesh is required. *posgen* will accept any GMSH¹⁰ formatted *triangle mesh*. The mesh must be non-intersecting and 2-manifold, but need not be closed - that is it must be a 2D surface, which can be physically realised. The mesh should additionally be consistently oriented, otherwise the mesh will be forced into a consistent orientation, and may end up reversed from the orientation that is actually desired.

The attributes for the proxigram itself include the maximum distance to which to compute the proxigram, maxdist, the file to which to save the histogram, outfile, and either a bin width, binwidth, or a bin count nbins (but not both). Note that the nbins value is only for one side of the proxigram. The mesh element is used to load the mesh from the specified file. This can optionally be recentred around the origin, but in most cases this will not be desired. At this time there is no capacity for generating the mesh using posgen. Please contact the author if you need to do this.

The proxigram may optionally include a <range file="someRangeFile"/> element, if provided the resultant proxigram will be computed for each species in the rangefile. If not provided, then only a count as a function of the distance from the surface will be given. An example is as follows:

8.9 Value transformations

8.9.1 pointconc

The point concentration operation computes a localised concentration using a ratio approach. This can allow for point-based identification of regions of differing composition, or compositional ratio. To compute compositions within a given radius, a valid rangefile must be supplied, as well as a listing of the numerator, and denominator species. With this list, the localised composition C_x will be computed, per point (x), as per the following equation:

$$C_x = \frac{\sum_{i=1}^{n} \text{Num}_i}{\sum_{j=1}^{m} \text{Denom}_j}$$
(3)

where n and m are the number of distinct numerator and denominator species respectively. The output value C_x will be assigned as the the new "m" value for each atom in the dataset.

Numerator and denominator species are specified in a <typelist>···</typelist> section, and both must be provided. Within the <typelist>···</typelist>, each species may be specified (if it is desired to be part of the numerator/denominator respectively), using an <atomtype symbol="symbol"/> element.

An example operation is given:

 $^{^{10} {\}tt http://geuz.org/gmsh}$

8.9.2 pointdensity

This operation computes the local density for each point in the dataset. This is done by placing a sphere around each point, of a specified radius, r. The number of points, N, that lie within this sphere are then counted and the density computed as $\rho = \frac{3N}{4\pi r^3}$, which is then used as the mass value for the point. Alternately if the count, N, is desired – rather than the sphere-normalised density (ρ) , the attribute normalise="false" can be given. An example of the use of the pointdensity operation is given:

```
<pointdensity radius="1.2" normalise="false"/>
```

Care must be taken when interpreting results from this operation. Points that lie on the exterior of the point cloud will have a lower density if there is a non-physical end to the point cloud (i.e. if there are locations in your data where more data should be, but your dataset stops). This effect is limited in distance from the free surface by r, and becomes more noticeable as r is increased. Discussion regarding analytical correction factors for these surface effects for some geometries can be found in Lei et al [4]. If desired, the $\operatorname{surfremove}$ can be used to remove these surface points automatically - however internal voids in the data will not be corrected.

10 Appendices

10.1 Glossary

- Attribute parameters that are given to an XML tag
- **DTD** Document Type Descriptor file . This file contains the formal syntax for operations, and is required for *posgen* to operate. DTDs are a standardised format.
- Element A node in an XML file, usually appears as <element> · · · </element> or <element/>.
- Operation An element in a *posgen* XML file that is an instruction to *posgen* to perform some action.
- POS file A file that stores X/Y/Z/Value data, with a specific binary format.
- TAPSIM A program for evaporation simulation in atom probe
- Tag Synonym for Element
- XML eXtensible Markup Language a simple structure for text files, which allows for simultaneous human and machine-readable files.

10.2 File formats

10.2.1 Pos Files

This file is a four-field fixed width record file, with an integer number of entries. The file is uncompressed raw 32 bit IEEE754 floating point data, and can be loaded using most languages relatively easily. Note that the order of the floating point numbers "endian-ness" is fixed as big-endian. The floating point values are X,Y,Z and an arbitrary scalar value (usually mass-to-charge). The file may not contain invalid (Not-a-Number "NaN") values.

10.2.2 Range Files

RNG (ORNL format) The program's interpretation of the Oak-Ridge format for range files is given below. The original specification is available in the book *Miller*, *Atom probe: Analysis at the atomic scale*, (Kluwer Academic/Plenum Publishers, ISBN 0306464152). Additional information on the format is given by the PoSaP program, which to the author's knowledge is not online. Unfortunately, the specification given for the file is weakly stated, and is open to different interpretations. It may be that there are alternate interpretations with which the authors are not familiar, and the code is thus unable to interpret — please report these.

A simple example file is given below, and is nominally in the ASCII 1 byte per character format. The original specification, to the authors knowledge, predates the UTF-8 and extended codepage support for non English languages. Thus non-English languages are not part of the file format - each should use the "C" locale for reading and writing, to avoid localisation concerns.

1 2 Aluminium Al 1 1 1 Al ----- Al . 10.0 150 1 . 150 200.2 1

The first line consists of two unsigned integers, separated by a space. The first integer is the number of unique ion types, and the second is the number of ranges. The next lines are taken as pairs. The first entry in the pair is the name of the "ion". The next entry consists of four parts. The first entry is a space terminated string, and is the shorthand name for the element. The next three elements are floating point values in the range of [0, 1], and are the colour of the ions that are ranged, with each element being

the red, green and blue component in turn (i.e. cubic RGB space). The final string is, to the authors' knowledge, unused, and is ignored.

This is repeated for each element pair, as specified by the first integer in the file. Each entry must be uniquely named, both in short and long names.

The next line can nominally be ignored, however it should contain the dash character from positions 1 to 13, followed by a space separated list (with leading space) of the short names, as specified above. Sequence positions are *not* obtained from the dash list, but rather from the order they appear in the file.

Following this is a 2D table (space separated). The first column appears vestigial. The second and third columns contain the start and end "range" values for each ion. Note that these do not have to be in the same sequence as the original specification. These range values must be non-overlapping, and can be any 32 bit floating point number (other than NaN).

The next columns are the range table, and specify which ions the range corresponds.

In the implementation here, the table should have only entries of 0 or 1, and the row (from column 3) should to exactly 1. Files where this is not the case may be accepted, however the entry will be treated as either a 0 or 1 value.

A more complex example is given below.

```
3 3
Magnesium
Mg 0.0 0.0 0.0
Copper
Cu 0.0 0.0 0.0
Nickel
Ni 0.0 0.0 0.0
------ Mg Cu Ni
. 25 27 1 0 0
. 25 33 0 1 0
. 55.6 59 0 0 1
```
